**Abstract:** This article presents an experimental study on the characterization of carbon steels, alloy steels, aluminum alloys, brass, and cast iron commonly used in the construction industry. The focus is on evaluating the mechanical properties of these materials through optical microscopy and Brinell hardness testing. A series of samples representing each material type were prepared and subjected to optical microscopy analysis to examine their microstructural characteristics. The images obtained were further analyzed using ImageJ software to measure the size of various microstructural constituents. Additionally, the Brinell hardness test was conducted on each sample to quantify their mechanical strength and resistance to indentation. The experimental results provide valuable insights into the microstructural characteristics and mechanical properties of these construction materials, aiding in the selection and design of appropriate alloys for specific construction applications. The findings also contribute to the broader understanding of carbon steels, alloy steels, Si-Al, brass and cast iron, offering potential improvements in construction material selection and performance.

Keywords: Carbon steels, alloy steels, characterization, construction material

#### **INTRODUCTION**

The construction industry heavily relies on a wide range of materials to meet the diverse demands of infrastructure development and structural integrity [1]. Among these materials, carbon steels, alloy steels, siluminates, brass, and cast-iron play crucial roles due to their favorable mechanical properties. Understanding the microstructural features and mechanical behavior of these materials is essential for ensuring their optimal performance in construction projects [2].

In this study, we aim to investigate the microstructural characteristics and mechanical properties of carbon steels, alloy steels, siluminates, brass, and cast iron through experimental testing. Optical microscopy, a widely used technique for examining material microstructures, will be employed to visualize and analyze the internal structures of the samples. By utilizing ImageJ software, we will

measure the size of various microstructural constituents, providing quantitative data on the microstructural features of these materials.

In addition to microstructural analysis, the Brinell hardness test will be conducted to assess the mechanical strength and resistance to indentation of the samples. The Brinell hardness value is a widely accepted measure of a material's ability to withstand external forces and is crucial in determining its suitability for construction applications.

The findings of this study will contribute to a comprehensive understanding of the microstructural features and mechanical properties of carbon steels, alloy steels, siluminates, brass, and cast iron. This knowledge will aid in the selection and design of materials for specific construction applications, ensuring optimal performance and durability. Moreover, the results will provide insights into potential improvements in construction material selection, leading to enhanced structural integrity and overall project success.

# OPTICAL MICROSCOPY TO CHARACTERIZE THE SAMPLES

#### **Preparation of samples**

The phase of sample preparation is a crucial step before commencing optical microscopy analysis for different materials. For C25 steel, C35, C40, 18MoCN13 alloy steel, Al-Si, and 45CuZn alloy, the samples need to undergo a series of preparation procedures. These include cutting the samples into desired shapes and sizes, followed by grinding and polishing to obtain a smooth surface. Next, the samples are etched with specific etchants, in our study we used Nital 2%, to reveal the microstructure and highlight any structural features.

On the other hand, for cast iron spheroidal graphite and cast-iron lamellar graphite, the preparation process involves cutting the samples, followed by mounting and polishing to achieve a flat surface. Subsequently, the samples are etched using suitable etchants to distinguish between spheroidal and lamellar graphite structures.

Proper sample preparation ensures accurate and reliable optical microscopy analysis, allowing for detailed examination of the microstructural characteristics and properties of these materials.

## **Optical microscopy**

Optical microscopy is a powerful technique used for the analysis of various materials: C25, C35, C40, 18MoCN13, and 45CuZn alloys. With optical microscopy, the samples can be examined at high magnification levels to observe their microstructural features. This technique utilizes visible light to illuminate the samples, which then interact with the material's structure, providing valuable information about grain boundaries, phase distribution, and defects. By using different objectives and lenses, optical microscopy allows for the visualization of fine details and the characterization of the material's composition. The size, shape, and distribution of grains can affect the strength, ductility, and toughness of the alloy.

The microstructure of carbon steel is mainly composed of ferrite and cementite, with the relative proportions of these phases depending on the carbon content, as shown in figure 1-3. While stainless steel can vary depending on the specific type, but it often includes ferrite, austenite (another iron-based crystal structure), and chromium carbide precipitates. A brittle iron-carbon alloy with a high carbon content is dominated by graphite (the stable form of carbon at cast iron's solidification temperatures) and ferrite or cementite, as presented in figure 5 and 6. The microstructure of brass can consist of alpha (a face-centered cubic solid solution) and beta (a body-centered cubic solid solution) phases, depending on the zinc content, as seen in figure 4. In the case of bronze can consist of alpha (a solid solution of tin in copper) and delta (an intermetallic compound of copper and tin) phases.

After completing the optical microscopy process, ImageJ is commonly utilized for further analysis and processing of the acquired images.

## **ImageJ Analysis**

ImageJ is a widely used image processing and analysis software that provides researchers with a powerful set of tools for working with digital images.

With ImageJ, we can perform a multitude of tasks such as image enhancement, filtering, segmentation, and measurement, the magnification scale used in our study is x200.

# **PRESENTATION OF RESULTS**

The tables (1 and 2) below present the results of size measurements conducted on various samples. For C25, C35, C40, 18MoCN13, and 45CuZn alloys, we measured the size by examining two diagonals, for each component of the structure, namely pearlite and ferrite. For cast iron with spheroidal graphite and cast iron with lamellar graphite we measured consecutively the diameter, and the length. We were unable to measure the size of Al-Si due to the complex shape of its microstructure. It is

important to note that a scale of (x200) was used and a conversion of 43.1 pixels corresponding to 0.002 mm was used for all the samples. Finally, we calculated the average grain size for all the samples in micrometers.

After measuring the grain size of the samples, the next step was to perform hardness tests to obtain the HB values. It is worth mentioning that, according to standards, we obtained a LD/HB ratio of 1.74.

Table 3. Average grain size measurement of spheroidal and lamellar graphite in micrometers

Cast Iron	403	231.84
Lamelar	366	210.55
Graphite	405	232.99

After calculating the average HB values for all the samples, we plotted a graph showing the HB values for each individual sample, as well as an average HB graph encompassing all the samples, as presented in figure.7.

Figure 7. Average HB values of samples

Hardness directly translates to a material's ability to resist permanent shape changes from scratches, indentation, abrasion, and erosion. The average HB values of all the samples fell within the range specified by the standards [3],[4],[5],[6],[7]. However, we were unable to conduct the test for C40 and spheroidal graphite samples due to their small measurement surfaces. Harder alloys have a longer lifespan because they can better withstand everyday wear and tear. This is important for products that need to last a long time, such as car parts, tools, and building materials.

# CONCLUSIONS

In this study, we conducted an experimental analysis to characterize the size and Brinell hardness of carbon steels, alloy steels, Si-Al alloys, and cast iron with spheroidal and lamellar graphite. Using optical microscopy, ImageJ software, and a hardness testing machine, we gained valuable insights into the microstructural features and mechanical properties of these materials.

Samples	Composition	Average grain size (µm)	Average Brinell hardness (HB)
C25	pearlite	0.878	185.70
	ferrite	0.525	-
C35	pearlite	0.984	168.33
	ferrite	0.785	-
C40	pearlite	0.578	84.57
	ferrite	0.485	-
18MoCN13	pearlite	1.228	68.23
	alloyed-ferrite	0.787	
45 CuZn Alloy	α	1.062	91.81
	β	1.398	-
Si-Al	-	-	79.73
Cast Iron	-	5.36	228.85
Lamelar Graphite spheroidal graphite	-	0.84	-

Table 4. Average grain size measurement and HB average of the samples

Based on the analysis of the results, it was observed that cast iron with lamellar graphite exhibited the highest hardness among the tested samples, indicating its superior resistance to deformation. On the

other hand, Si-Al alloys displayed relatively lower hardness values, suggesting their lower mechanical strength compared to the other materials examined.

The importance of this study in the field of construction lies in its contribution to material selection and design. By characterizing the microstructural features and mechanical properties of carbon steels, alloy steels, Si-Al alloys, and cast iron, construction professionals can make informed decisions regarding the appropriate materials for specific applications. Understanding the relative hardness and strength of these materials enables engineers and designers to ensure the structural integrity and durability of construction projects.

Furthermore, this study provides a foundation for further research and development in the field of construction materials. Future investigations can focus on exploring methods to enhance the mechanical properties of Si-Al alloys, making them more suitable for construction applications. Additionally, the findings can inform the development of new alloys or the modification of existing ones to optimize their performance in construction projects.
